Introduction:
Encephalocele is defined as protrusion of cranial contents like meninges and cerebral tissue beyond the normal confines of the skull through a defect in the cranium. The population incidence of this congenital anomaly is estimated to vary from 1 per 300 to 1 per 10000 live births¹⁻⁴. In respect to the incidence, cranial dysraphism, particularly encephaloceles, is far less common compared to its spinal counterpart, namely, myelomeningocele, accounting for only 8 to 19% of all dysraphism⁴⁻⁹.

It is one form of a neural tube defect as are anencephaly and spina bifida ¹⁰. There are 2 main types of encephalo-meningocele, frontoethmoidal and occipital, according to the location of the defect. The frontoethmoidal type defect, which is located in the area of the frontal and ethmoidal bones, is exclusively common in Southeast Asia¹¹. There has been no consensus about the etiology, prognosis-related classification, or surgical strategy for encephalo-meningocele.

The aim of surgical treatment is to restore the functional brain tissue in the cranial cavity by performing dural repair with the correction of bone defect and restoration of esthetic facial appearance safely and successfully in a single stage. We had managed a case successfully in a one stage operation for giant Sfrontonasal encephalocele in a very young child.

Case Presentation:
A 8 month-old female child was admitted to our hospital, presented with a protruding soft swelling with a wide base between the eyes (Figure 1 a,b). According to his mother’s description, he had been born with the facial swelling. It had slowly enlarged as he grew up. Giant swelling is almost obscured eyes. No congenital anomalies were mentioned in his siblings. The physical examination revealed non-pulsatile giant swelling near the nasal bridge, between the medial canthus with underlying bony defect, interorbital hypertelorism, long-nose deformity and medial canthal dystopia. The neurological status revealed no abnormalities.
Neuroimaging studies
He was investigated with CT-scan of the head (Fig.IV,V) that showed a defect in the anterior cranial base involving the crista galli and between frontal and nasal bone. The defect directly communicated with the anterior cranial fossa through which herniated brain could be seen extending through nasal bridge. The size and anatomical location of the lesion were noted. Associated findings such as, head size, any underlying hydrocephalus were also noted.

Operation and postoperative courses: In this cases a combined approach was used was scheduled for single stage surgery for repair of dura. Craniotomy and repair from inside was done. We made a bicoronal scalp incision down to the anterior of the tragus. A paranasal skin incision was made in a reversed Y-shape because of the bilateral herniated masses in order to remove any redundant skin. The scalp was reflected to expose frontal bone, both supra orbital rims nasal bridge with bony defect. A typical
bifrontal craniotomy and a T shaped frontonasal osteotomy were done to obtain adequate exposure to the encephalomeningoeles. Supra orbital rim was removed. A satisfactory extradural exposure all around the herniating glioting brain was thus achieved. The margins were freed all around the bony defect. The skull defects over the inner wall of the orbit and ethmoidal sinus were located, and the herniated dural sac and the degenerative brain tissue it contained were resected. Watertight and durable closure of the dural defect was achieved. All areas were fixed with 2-0 prolene. The medial canthus was repositioned with prolene 3-0 stay sutures. After achieving haemostasis, wounds were closed in layers. Postoperatively, patient recovered uneventfully except there was subgaleal CSF collection in postoperative period (3rd POD) and resolved spontaneously. A good cosmetic result had been achieved after operation (Fig.-3).

Discussion:
From the anatomic aspect, the most common sites for encephaloceles are occipital and fronto-nasal regions. In Asia and Africa, there is a predominance of the fronto-nasal group while 80-90% are found in the occipital region in the Western Hemisphere. Approximately 70% of occipital encephaloceles occur in females, but there is no sex predominance noted in the frontobasal type. The incidence of hydrocephalus in patients with encephaloceles is reported to be about 50.0%. In planning the strategy of management of encephalocele, one needs to take into consideration the site, size, contents, state of CSF pathway, neurological status, associated anomalies and overall general condition of the patient. In both our cases, there was a fronto-orbito-nasal defect extending posteriorly up to crista galli with mild hypertelorism and cosmetic deformity.

The principle of repair is analogous to the management of hernias in general surgery, which includes dissection of the sac, isolation of the neck, adequate closure at the neck and reinforcement. The herniated part of the brain is usually gliosed and non-viable and can usually be safely amputated. Dural defect should be closed in a watertight fashion, using graft if necessary. In our case, watertight and durable closure of the dural defect was achieved by an autologous pericranial graft and fibrin glue. Ideally, reinforcement of bony defect with bone graft (split cranium, split rib, or acrylic) will prevent reprotrusion through the defect. Reconstruction of bony abnormalities may be necessary at times for better cosmetic results. Associated hydrocephalus should be treated by shunting before managing the encephalocele. As mentioned before, surgical approaches for encephaloceles, based on its location and type, can be direct, indirect or both. In 2 cases, our operative approach involved combined approach (bifrontal craniotomy and direct repair) and were performed in collaboration with the Maxillofacial surgeon. We performed a typical bifrontal craniotomy with a T-shaped osteotomy for 1-stage reconstruction and obtained adequate exposure in order to perform dura repair and the encephalomeningocele resection.

The end result of encephalocele surgery is usually not determined by the neurosurgical procedure per se, but by the underlying brain involvement and presence or absence of other congenital defects. In long-term follow up, cases with anterior defect have better prognosis and more than half have normal intelligence quotient (IQ)\(^{12}\).

Instead of the traditional 2-stage correction by preliminary disconnection and subsequent extracranial correction of the facial deformity\(^{13}\), a 1-stage operation has become the standard treatment\(^{14-15}\). Most Neurosurgeons and craniofacial surgeons prefer the combined nasal-coronal approach with a frontal craniotomy because of the wide exposure\(^{14}\). On the other hand, the frontal bone flap can also be remodeled to eliminate the trigonocephalic bulge\(^{16}\), repair any external skull defects, and restore an esthetic appearance such as with nasal augmentation.

Conclusion:
Encephalocele is a relatively uncommon neurosurgical entity largely seen in the pediatric population. Treatment of this condition can be rewarding if properly managed early. Occipital type may be approached without opening the cranium, while sincipital and basal encephaloceles usually require craniotomy. In this paper we present our experience in the operative management of frontonasal encephalocele with good outcome and also share our recommendation in technical consideration for surgical approaches.
